

Butorphanol

Revised: December 15, 2023.

CASRN: 42408-82-2

Drug Levels and Effects

Summary of Use during Lactation

Maternal use of oral opioids during breastfeeding can cause infant drowsiness, which may progress to rare but severe central nervous system depression. Limited data indicate that butorphanol is excreted into breastmilk in small amounts. Butorphanol is poorly orally absorbed, so it is unlikely to adversely affect the breastfed infant. Monitor the infant for drowsiness, adequate weight gain, and developmental milestones, especially in younger, exclusively breastfed infants. If butorphanol is required by the mother of a newborn, it is not a reason to discontinue breastfeeding; however, once

the mother's milk comes in, it is best to provide pain control with a nonnarcotic analgesic and limit maternal intake to 2 to 3 days with close infant monitoring. If the baby shows signs of increased sleepiness (more than

usual), difficulty breastfeeding, breathing difficulties, or limpness, a physician should be contacted immediately. Labor pain medication may delay the onset of lactation. Because there is no published experience with repeated, high, intravenous or intranasal doses of butorphanol during breastfeeding, other agents may be preferred in these situations, especially while nursing a newborn or preterm infant

Drug Levels

In adults, the oral bioavailability of butorphanol is 17% while the intranasal bioavailability is 70%. Butorphanol is metabolized to inactive metabolites. Intranasal and parenteral doses of 25 to 30 mcg/kg have been used in infants as young as 6 months for postoperative analgesia.

Maternal Levels. Twelve lactating women were given a single butorphanol dose at 2 to 4 days postpartum. Six of these women were given a 2 mg single intramuscular dose and 6 others were given a single 8 mg oral dose. Milk was sampled 3 times after the dose. The reported average milk levels were 1.5, 0.7 and 0.3 mcg/L at 2, 4 and 8 hours, respectively, after the 2 mg intramuscular dose. The average milk levels after the 8 mg oral dose were 3.6, 1.8 and 1.1 mcg/L at 3, 5 and 8 hours, respectively. The half-life of elimination from milk was about 2 hours.[1] Using the data from this study, doses of butorphanol 2 mg intramuscularly or 8 mg orally will result in average milk levels of 0.7 and 2 mcg/L, respectively, over 8 hours after the dose. Using these calculated average milk levels, an exclusively breastfed infant would receive 0.035 mcg/kg from a 2 mg intramuscular maternal dose of butorphanol, and 0.1 mcg/kg from an 8 mg oral maternal dose of butorphanol, from milk ingested up through 8 hours after the dose. These amounts represent 0.11% and 0.08% of the maternal weight-adjusted dosages, respectively.

Infant Levels. Relevant published information was not found as of the revision date.

Effects in Breastfed Infants

Relevant published information was not found as of the revision date.

Effects on Lactation and Breastmilk

Narcotics and narcotic agonist-antagonists can increase serum prolactin.[2,3] However, the prolactin level in a mother with established lactation may not affect her ability to breastfeed.

A study compared women who received butorphanol or nalbuphine during labor (n = 26) to those who received no analgesia (n = 22). The time to effective breastfeeding was longer (46.5 minutes) in the analgesia group than in the no analgesia group (35.4 minutes).[4]

A national survey of women and their infants from late pregnancy through 12 months postpartum compared the time of lactogenesis II in mothers who did and did not receive pain medication during labor. Categories of medication were spinal or epidural only, spinal or epidural plus another medication, and other pain medication only. Women who received medications from any of the categories had about twice the risk of having delayed lactogenesis II (>72 hours) compared to women who received no labor pain medication.[5]

Alternate Drugs to Consider

Acetaminophen, Hydromorphone, Ibuprofen, Morphine, Nalbuphine
